Heterogeneous Downward Nominal Wage Rigidity: Foundations of Phillips’s Phillips Curve

Stephanie Schmitt-Grohé†       Martín Uribe‡

This draft August 10, 2023

Abstract

The new-Keynesian wage Phillips curve is forward-looking because workers have market power. This assumption is unappealing for economies without significant labor unions. We propose a model in which workers are price takers and there is heterogeneous downward nominal wage rigidity for individual labor varieties. The model delivers a non-forward-looking nonlinear Phillips curve linking current wage inflation and unemployment. Although the equilibrium features occasionally binding constraints for individual labor types, there are no such constraints in the aggregate making the model amenable to perturbation analysis. The predicted dynamics closely resemble those of the new-Keynesian model putting in perspective the market power assumption.

Keywords: Downward nominal wage rigidity, wage Phillips curve, new-Keynesian model, heterogeneity.

1 Introduction

Since its conception in 1958, the Phillips curve has been the focus of intense research activity in macroeconomics. In its original formulation, Phillips (1958) conceived it as a contemporaneous empirical relationship between wage inflation and unemployment. The new-Keynesian model, which has arguably been the predominant framework for economic analysis since the 1990s, introduces a forward-looking component into the Phillips curve. In this class of models, wage inflation is related not only to the rate of unemployment but also to expected future wage inflation. This paper addresses two related questions. First, is the forward-looking component in the wage Phillips curve a necessary feature of models with nominal rigidity and forward-looking rational agents? And second, if not, would a model featuring a non-forward-looking wage Phillips curve have significantly different dynamic properties?

The reason why the new-Keynesian model generates an expectations augmented wage Phillips curve is that it assumes that workers have market power. This assumption together with the assumption of nominal wage rigidity implies that the wage setting decision is forward looking, as today’s nominal wage choice impacts the entire expected future path of the worker’s real wage. The assumption that workers have market power can be justified in economies with a strong presence of labor unions. However, it is less tenable in economies, like the United States, in which secularly a small fraction of the labor force is unionized. For this reason in the present paper we do away with the assumption that workers have market power.

We propose a model in which downward nominal wage rigidity varies in intensity across a continuum of labor varieties. The nominal wage of each labor variety is bounded below by the average wage prevailing in the previous period times a variety-specific scalar. In all respects other than the heterogeneity of downward nominal wage rigidity, the model economy is standard; households and firms operate in competitive markets and are rational and forward looking. We show that in equilibrium the model delivers a non-forward-looking non-linear wage Phillips curve. An increase in wage inflation raises the fraction of labor varieties that are not constrained by the wage lower bound. As a result, the fraction of the labor force suffering involuntary unemployment falls. Taken together, these effects imply a negative relationship between current wage inflation and current unemployment. The model thus provides microfoundations to Phillips’s celebrated empirical relation.

A second important result of the paper is that for standard calibrations of the model, its implied equilibrium dynamics are qualitatively and quantitatively similar to those of the new-Keynesian model of wage stickiness. An implication of this result is that the assumption that workers have market power, which is responsible for the emergence of an expectations-
augmented wage Phillips curve in the new-Keynesian model, does not appear to play a crucial role.

A third contribution of the paper is to show that the proposed model with heterogeneous downward nominal wage rigidity is amenable to perturbation analysis, which facilitates computation of the equilibrium dynamics. The standard model of downward nominal wage rigidity, in which the wage lower bound is homogeneous across workers, features an occasionally binding constraint at the aggregate level. This property makes that model not suitable to be analyzed with perturbation methods. In the proposed model, although there are occasionally binding constraints at the level of individual labor varieties, in the aggregate the equilibrium conditions do not feature such restrictions.

This paper is related to a large literature on the role of nominal wage rigidity for macroeconomic adjustment. As mentioned, the starting point is the empirical estimate by Phillips (1958) of a negative relation between wage inflation and unemployment. In the context of the new-Keynesian framework, sticky wages à la Calvo was introduced by Erceg, Henderson, and Levin (2000). The derivation of a wage Phillips curve in the context of that model is presented in Galí (2011) and Casares (2010). These authors show that the implied wage Phillips curve is forward looking. Kim and Ruge-Murcia (2009) study a model with nominal wage rigidity à la Rotemberg but with an asymmetric wage adjustment cost function. They estimate the parameters of this cost function and find that wage cuts are more costly than wage increases. However, the implied wage Phillips curve, independently of the asymmetry, is forward looking. Elsby (2009) and Benigno and Ricci (2011) study downward nominal wage rigidity in the context of models in which workers have monopoly power and set wages in a forward looking fashion. These assumptions introduce a forward-looking component into the Phillips curve. Unlike in these studies, in the present paper workers are price takers and consequently the implied wage Phillips curve does not include a forward-looking component. Schmitt-Grohé and Uribe (2016, 2017) study the implications of downward nominal wage rigidity for macroeconomic adjustment in dynamic general equilibrium models of the open and closed economy. Unlike in the present formulation, in these studies the lower bound on nominal wages is invariant across labor varieties. The framework proposed here nests this class of model as a special case. A further difference with these two studies is that they are not amenable to perturbation analysis because the aggregated equilibrium conditions feature an occasionally binding constraint. There is also a literature combining labor search frictions and nominal rigidities including Faia (2008), Gertler, Sala, and Trigari (2008), and Dupraz, Nakamura, and Steinsson (2022). Relative to this literature the present paper does not consider search frictions. Instead the source of involuntary unemployment is a labor variety specific form of downward nominal wage rigidity. Benigno and Eggertsson (2023) add
downward nominal wage rigidity to a new Keynesian model with labor search frictions and find that the predicted Phillips curve, relating price inflation to labor market tightness (the ratio of vacancies to unemployed workers) has a kink. This study shares with the present paper the finding that downward nominal wage rigidity can give rise to a non-linear Phillips curve but differs in that the Phillips curve is in prices rather than wages and has a forward looking component.

The empirical relevance of downward nominal wage rigidity has been extensively documented by, among others, Card and Hyslop (1996), Kahn (1997), Gottschalk (2005), Barattieri, Basu, and Gottschalk (2014), Daly and Hobijn (2014), Schmitt-Grohé and Uribe (2016), and Jo (2022). Finally, empirical estimates of the wage Phillips curve are presented in Galí (2011) and Galí and Gambetti (2019). We use the latter of these two papers to discipline our quantitative analysis.

The remainder of the paper is organized as follows. Section 2 presents the model with heterogeneous downward nominal wage rigidity. This section also shows that the equilibrium conditions do not include occasionally binding constraints in the aggregate, allowing for a characterization of the equilibrium using perturbation methods. Section 3 analyzes the short- and long-run Phillips curves implied by the proposed model. Section 4 shows that for standard calibrations the equilibrium dynamics implied by the model with heterogeneous downward nominal wage rigidity are similar to those of the new-Keynesian model of wage rigidity. Section 5 concludes.

2 The Model

To focus on the modeling of heterogeneous downward nominal wage rigidity, we first present an economy with inelastic labor supply. Section 4.1 below analyzes the economy with endogenous labor supply.

2.1 Firms

Firms are price takers. They use labor as the sole input to produce a final good. Profits are given by

\[ P_t z_t F(h_t) - W_t h_t, \]

where \( P_t \) denotes the product price level, \( h_t \) denotes labor, \( W_t \) denotes the nominal wage rate, \( z_t \) is an exogenous productivity shock, and \( F(\cdot) \) is an increasing and concave production
function. The optimality condition determining the demand for labor is

$$z_t F'(h_t) = \frac{W_t}{P_t},$$

(1)

which equates the marginal product of labor to the real wage.

The labor input $h_t$ is assumed to be a composite of a continuum of labor varieties $h_{jt}$ for $j \in [0, 1]$. The aggregation technology is of the form

$$h_t = \left[ \int_0^1 h_{jt}^{1-\eta} dj \right]^{1/(1-\eta)},$$

(2)

where $\eta > 0$ is the elasticity of substitution across labor varieties. The firm chooses the quantity of each labor variety $h_{jt}$ to minimize its total labor cost, $\int_0^1 W_{jt} h_{jt} dj$, subject to the aggregation technology (2), given its desired amount of the labor composite $h_t$ and taking as given the wage of each variety of labor, denoted $W_{jt}$. This cost minimization problem yields the demand for labor of type $j$,

$$h_{jt} = \left( \frac{W_{jt}}{W_t} \right)^{-\eta} h_t,$$

(3)

where

$$W_t = \left[ \int_0^1 W_{jt}^{1-\eta} dj \right]^{1/(1-\eta)}$$

(4)

is the cost-minimizing price of one unit of aggregate labor, that is, when $h_{jt}$ is chosen optimally, $W_t$ satisfies $W_t h_t = \int_0^1 W_{jt} h_{jt} dj$. Firms are assumed to be always on their demand schedules for labor varieties.

### 2.2 Households

The representative household has preferences over streams of consumption, denoted $c_t$, described by the utility function

$$E_0 \sum_{t=0}^{\infty} \beta^t U(c_t),$$

where $\beta \in (0, 1)$ is a subjective discount factor, and $U(\cdot)$ is an increasing and concave period utility function. The household supplies inelastically $h$ units of labor of each variety $j \in [0, 1]$. We endogenize the supply of labor in section 4.

The economy faces an exogenous natural rate of unemployment denoted $u^n$. The natural rate of unemployment reflects frictions in the labor market unrelated to nominal rigidity.
The effective supply of labor variety \( j \), is then given by

\[ h_{jt} \leq \bar{h}(1 - u^n_t). \]  

Employment of each variety of labor is demand determined, so the household takes \( h_{jt} \) as given. Sometimes the household will not be able to sell all the units of labor it supplies. In these circumstances, it will suffer involuntary unemployment above the natural rate.

Each period \( t \geq 0 \), households can trade a nominally risk free discount bond denoted \( B_t \) that pays the interest rate \( i_t \) when held between periods \( t \) and \( t + 1 \). In addition, each period the household pays real lump-sum taxes in the amount \( \tau_t \) and receives profits from the ownership of firms in the amount \( \phi_t \). Its sequential budget constraint is then given by

\[ c_t + \frac{B_t/P_t}{1 + i_t} + \tau_t = \int_0^1 \frac{W_{jt}}{P_t} h_{jt} dj + \frac{B_{t-1}/P_{t-1}}{1 + \pi_t} + \phi_t, \]

where

\[ \pi_t = \frac{P_t}{P_{t-1}} - 1 \]

denotes the inflation rate. The household chooses contingent plans for bond holdings and consumption to maximize its lifetime utility subject to its sequential budget constraint and some no-Ponzi game borrowing limit. The optimality conditions associated with consumption and bond holdings give rise to the Euler equation

\[ U'(c_t) = \beta(1 + i_t)E_t^U U'(c_{t+1}) / (1 + \pi_{t+1}). \]  

We now turn to a description of our proposed form of nominal rigidity, which is the novel element of the model.

### 2.3 Heterogeneous Downward Nominal Wage Rigidity

Each period \( t \geq 0 \), the nominal wage of every variety \( j \in [0, 1] \) is assumed to be subject to a lower bound constraint of the form

\[ W_{jt} \geq \gamma(j) W_{t-1}, \]

where \( \gamma(j) \) is a positive and increasing function governing the degree of downward nominal wage rigidity of labor variety \( j \). This formulation of downward nominal wage rigidity nests the homogeneous case studied in Schmitt-Grohé and Uribe (2016), which obtains when the function \( \gamma(j) \) is independent of \( j \). Note that the wage lower bound depends on the past
aggregate wage rate, $W_{t-1}$, and not on the nominal wage paid on labor of type $j$ in the previous period, $W_{jt-1}$. As will become clear shortly, this formulation facilitates aggregation. The function $\gamma(\cdot)$ need not be interpreted as representing a fixed ordering of labor varieties. For example, welders could be represented by $j = 0.45$ in period $t$ and by $j = 0.73$ in $t + 1$. This could occur, for example, because welders unionized in $t + 1$ or because they completed wage-bargaining negotiations with employers’ representatives in that period.

We close the labor market with a slackness condition imposed at the level of each labor variety,

$$[\tilde{h}(1 - u^n_t) - h_{jt}][W_{jt} - \gamma(j)W_{t-1}] = 0. \tag{9}$$

According to this condition, when an occupation suffers unemployment above the natural rate, the wage rate must be stuck at its lower bound. The slackness condition also says that if in a given occupation the wage rate is above its lower bound, then the occupation must display full employment, defined as an unemployment rate equal to the natural rate.

### 2.4 The Government

The central bank sets the nominal interest rate according to a Taylor rule of the form

$$1 + i_t = \frac{1 + \pi^*}{\beta} \left(1 + \frac{\pi_t}{1 + \pi^*}\right)^{\alpha_\pi} \left(\frac{y_t}{y}\right)^{\alpha_y} \mu_t, \tag{10}$$

where $\pi^*$ denotes the central bank’s inflation target, $y_t$ denotes aggregate output, $y$ denotes the steady-state value of $y_t$, $\alpha_\pi$ and $\alpha_y$ are parameters, and $\mu_t$ is an exogenous and stochastic monetary shock.

We assume that fiscal policy is passive in the sense that government solvency is satisfied independently of the path of the price level.

### 2.5 Equilibrium

In equilibrium, aggregate output is given by

$$y_t = z_t F(h_t). \tag{11}$$

Market clearing in the goods market requires that consumption equal output,

$$c_t = y_t. \tag{12}$$

We are now ready to define a competitive equilibrium.
Definition 1 (Competitive Equilibrium) A competitive equilibrium is a set of processes \( c_t, y_t, h_t, h_{jt}, W_t, W_{jt}, P_t, \pi_t, \) and \( i_t \) satisfying (1) and (3)-(12) for all \( j \in [0,1] \) and \( t \geq 0 \), given the initial wage \( W_{-1} \) and the exogenous disturbances \( z_t, \mu_t, \) and \( u^i_t \).

Next, we show that the equilibrium conditions can be written in terms of a single labor variety. A by-product of this analysis is a demonstration that the model delivers a static wage Phillips curve.

### 2.6 Equilibrium in \( j^* \) Form

We consider an equilibrium in which for every \( t \geq 0 \) there exists a cut-off labor variety denoted \( j^*_t \in (0,1) \) that operates at full employment, \( h_{jt} = \bar{h}(1 - u^i_t) \) for \( j = j^*_t \), and for which the wage lower bound holds with equality, \( W_{j^*_t} = \gamma(j^*_t)W_{t-1} \). Evaluating the labor demand (3) at \( j = j^*_t \), yields the condition

\[
\bar{h}(1 - u^i_t) = \left( \frac{\gamma(j^*_t)}{1 + \pi^t_W} \right)^{-\eta} h_t, \tag{13}
\]

where

\[
\pi^t_W \equiv \frac{W_t}{W_{t-1}} - 1 \tag{14}
\]

denotes wage inflation in period \( t \).

Because \( \gamma(j) \) is strictly increasing, it follows that all varieties \( j < j^*_t \) must also pay the wage \( \gamma(j^*_t)W_{t-1} \), and thus operate at full employment. To see this, let \( W^*_t \equiv \gamma(j^*_t)W_{t-1} \) and suppose first, contrary to the claim, that \( W_{jt} < W^*_t \) for some \( j < j^*_t \). Then, by (3) we have that \( h_{jt} = (W_{jt}/W_t)^{-\eta} h_t > (W^*_t/W_t)^{-\eta} h_t = \bar{h}(1 - u^i_t) \), which violates the time constraint (5).

Suppose now that, contrary to the claim, \( W_{jt} > W^*_t \) for some \( j < j^*_t \). Then by the same logic \( h_{jt} < \bar{h}(1 - u^i_t) \). Further, \( W_{jt} > W^*_t = \gamma(j^*_t)W_{t-1} > \gamma(j)W_{t-1} \). So we have that in this case \( \bar{h}(1 - u^i_t) - h_{jt} > 0 \) and \( W_{jt} - \gamma(j)W_{t-1} > 0 \), which violates the slackness condition (9).

It also follows that all labor varieties \( j > j^*_t \) are stuck at their wage lower bound and suffer involuntary unemployment. To see this, use (3) and (8) to write, for any \( j > j^*_t \),

\[
h_{jt} = (W_{jt}/W_t)^{-\eta} h_t \leq (\gamma(j)W_{t-1}/W_t)^{-\eta} h_t < (\gamma(j^*_t)W_{t-1}/W_t)^{-\eta} h_t = \bar{h}(1 - u^i_t). \]

This shows that all labor varieties \( j > j^*_t \) suffer involuntary unemployment above the natural rate. It then follows immediately from the slackness condition (9) that \( W_{jt} = \gamma(j)W_{t-1} \), that is, wages of all labor varieties \( j > j^*_t \) are stuck at their lower bounds.

Summing up, in the equilibrium we are considering, we have that

\[
\begin{align*}
    h_{jt} &= \bar{h}(1 - u^i_t) \quad \text{and} \quad W_{jt} = \gamma(j^*_t)W_{t-1} \quad \text{for} \ j \leq j^*_t \\
    h_{jt} &= \bar{h}(1 - u^i_t) \quad \text{and} \quad W_{jt} = \gamma(j)W_{t-1} \quad \text{for} \ j > j^*_t.
\end{align*}
\]
The cut-off variety $j^*_t$ is an important object in this model because it governs the extensive margin of unemployment, that is, how many occupations will operate below potential.

Next, we analyze the determination of $j^*_t$ in general equilibrium. To this end, write the wage aggregation equation (4) as

$$W_t^{1-\eta} = \int_0^{j^*_t} W_{jt}^{1-\eta} dj$$
$$= \int_0^{j^*_t} [\gamma(j^*_t)W_{t-1}]^{1-\eta} dj + \int_{j^*_t}^1 [\gamma(j)W_{t-1}]^{1-\eta} dj$$
$$= W_{t-1}^{1-\eta} \left[ j^*_t \gamma(j^*_t)^{1-\eta} + \int_{j^*_t}^1 \gamma(j)^{1-\eta} dj \right].$$

Using the definition of wage inflation given in (14) and rearranging gives

$$(1 + \pi^W_t)^{1-\eta} = j^*_t \gamma(j^*_t)^{1-\eta} + \int_{j^*_t}^1 \gamma(j)^{1-\eta} dj. \tag{15}$$

According to this expression, wage inflation is increasing in the cut-off labor variety $j^*_t$. To understand why, suppose that the cut-off variety increases from $j^*_t'$ to $j^*_t'' > j^*_t'$. Then, all varieties from 0 to $j^*_t'$ are unconstrained before and after the increase in $j^*_t$. As a result, their wages increase from $\gamma(j^*_t')W_{t-1}$ to $\gamma(j^*_t'')W_{t-1}$. Varieties $j$ between $j^*_t'$ and $j^*_t''$ were constrained before the change and become unconstrained after. For these workers, the wage rate increases from $\gamma(j)W_{t-1} < \gamma(j^*_t'')W_{t-1}$ to $\gamma(j^*_t'')W_{t-1}$. Finally labor varieties $j > j^*_t''$ are constrained before and after the change in $j^*_t$, so their wages remain unchanged. It follows that the average wage increases.

We are now ready to define the competitive equilibrium in $j^*_t$ form.

**Definition 2 (Competitive Equilibrium in $j^*_t$ Form)** A competitive equilibrium is a set of processes $j^*_t$, $y_t$, $h_t$, $w_t \equiv W_t/P_t$, $i_t$, $\pi_t$, and $\pi^W_t$, satisfying

$$y_t = z_t F(h_t), \tag{16}$$
$$U'(y_t) = \beta(1 + i_t) E_t \frac{U'(y_{t+1})}{1 + \pi_{t+1}}, \tag{17}$$
$$z_t F'(h_t) = w_t, \tag{18}$$
$$1 + i_t = \frac{1 + \pi^*}{\beta} \left( \frac{1 + \pi_t}{1 + \pi^*} \right)^{\alpha_x} \left( \frac{y_t}{y} \right)^{\alpha_y} \mu_t, \tag{19}$$
$$1 + \pi^W_t = \frac{w_t}{w_{t-1}} (1 + \pi_t). \tag{20}$$
\[ h(1 - u_t^n) = \left( \frac{\gamma(j_t^*)}{1 + \pi_t^W} \right)^{-\eta} h_t, \] (21)

and
\[ (1 + \pi_t^W)^{1-\eta} = j_t^* \gamma(j_t^*)^{1-\eta} + \int_{j_t^*}^{1} \gamma(j)^{1-\eta} dj, \] (22)
given the initial condition \( w_{-1} \) and the stochastic processes \( z_t, \mu_t, \) and \( u_t^n. \)

Equilibrium conditions (16)–(20) are standard components of optimizing monetary models, with or without nominal rigidity. The Keynesian features of the model appear in the last two equilibrium conditions. Equation (21) says that there is one labor variety, \( j_t^* \), for which there is full employment and the wage constraint just binds. Equation (22) says that wage inflation is a weighted average of the wage increase across varieties relative to the average wage prevailing the previous period. For equation (22) to hold with equality at all times it must be the case that in equilibrium wage inflation be neither too high nor too low so as to rule out the corner solutions \( j_t^* = 0 \) and \( j_t^* = 1. \)\(^1\) Taken together, these conditions leave the door open for monetary disturbances to have real effects. To see this, it suffices to consider, as an example, a situation in which the economy is initially in steady state and in period 0 experiences an unexpected purely transitory fall in the monetary disturbance \( \mu_t. \) After the shock there is perfect foresight. Suppose, contrary to the claim, that the fall in \( \mu_t \) does not affect the real allocation (\( y_t \) or \( h_t \)). Then, by the Euler equation (17) and the Taylor rule (19), we have that the inflation rate \( \pi_t \) must change either at \( t = 0 \) or at \( t = 1 \) or both. Also, by the labor demand (18), the real wage \( w_t \) must stay constant, otherwise \( h_t \) would move. Then, by (20), wage inflation \( \pi_t^W \) must change either at \( t = 0 \) or at \( t = 1 \) or both. In turn, by (21), \( j_t^* \) must change either at \( t = 0 \) or at \( t = 1 \) or both and the ratio \( \gamma(j_t^*)/(1 + \pi_t^W) \) must stay constant, otherwise \( h_t \) would be affected. The latter implication requires \( \gamma'(j) \neq 0. \) But, according to (22), the ratio \( \gamma(j_t^*)/(1 + \pi_t^W) \) can stay constant only if \( \gamma'(j) = 0, \) which is a contradiction.

\(^1\)As will become clear, for equilibrium dynamics in a neighborhood around the deterministic steady state, ruling out the corner solutions requires that \( \left[ \int_0^1 \gamma(j)^{1-\eta} dj \right]^{1/(1-\eta)} < 1 + \pi^* < \gamma(1). \)
3 The Wage Phillips Curve

The aggregate unemployment rate, denoted \( u_t \), is given by the integral of the unemployment rates across all labor varieties. Formally,

\[
\begin{align*}
    u_t & \equiv \bar{h}^{-1} \int_0^1 (\bar{h} - h_{jt})dj \\
    &= u^n_t j_t^* + \bar{h}^{-1} \int_{j_t^*}^1 (\bar{h} - h_{jt})dj \\
    &= u^n_t j_t^* + (1 - j_t^*) - \frac{h_t}{h} \int_{j_t^*}^1 \left( \frac{W_{jt}}{W_t} \right)^{-\eta} dj \\
    &= u^n_t j_t^* + (1 - j_t^*) - \left( \frac{W_{t-1}}{W_t} \right)^{-\eta} h_t \int_{j_t^*}^1 \gamma(j)^{-\eta} dj.
\end{align*}
\]

Using the definition of wage inflation given in (14) and equilibrium condition (21) to eliminate \((W_{t-1}/W_t)^{-\eta} h_t\), we can write

\[
u_t = u^n_t + (1 - u^n_t) \left[ (1 - j_t^*) - \int_{j_t^*}^1 \left( \frac{\gamma(j)}{\gamma(j_t^*)} \right)^{-\eta} dj \right]. \tag{23}
\]

The right hand side of equation (23) is decreasing in \( j_t^* \). It follows that as \( j_t^* \) increases, the unemployment rate falls. This is intuitive because all activities below the cut-off threshold \( j_t^* \) operate at full employment, so the higher the cut-off threshold is, the smaller the set of activities displaying involuntary unemployment above the natural rate will be.

Given the natural rate of unemployment, \( u^n_t \), equations (22) and (23) implicitly represent a contemporaneous relationship involving only unemployment and wage inflation \((u_t \text{ and } \pi_W^t)\). Further, \( u_t \) and \( \pi_W^t \) are negatively related. To see this, recall that equation (22) implies that an increase in wage inflation allows for a larger set of labor varieties to be unconstrained by the wage lower bound (i.e., an increase in wage inflation raises the cut-off variety \( j_t^* \)). In turn, equation (23) says that the larger the set of unconstrained labor varieties is, the lower unemployment will be. Thus, the model’s implied relationship between unemployment and wage inflation represents a downward sloping wage Phillips curve. This relationship captures the idea, often used in the early empirical literature on downward nominal wage rigidity, that inflation greases the wheels of the labor market (e.g., Card and Hyslop, 1997).\(^2\)

We note that the wage Phillips curve implied by the model is static. In particular, it does not feature future expected inflation. In this sense, the present model departs from

\(^2\)The phrase “inflation greases the wheels of the labor market” is often attributed to Tobin (1972), although that paper does not explicitly use it.
the new-Keynesian framework in which the wage Phillips curve is forward looking (Erceg, Henderson, and Levin, 2000; Galí, 2011) and can be interpreted as providing microfoundations to Phillips’s original formulation of a static wage Phillips curve (Phillips, 1958). The following proposition summarizors this result.

**Proposition 1 (Phillips’s Phillips Curve)** *The model with heterogeneous downward nominal wage rigidity implies a static negative relation between wage inflation, \( \pi_t^W \), and the unemployment rate, \( u_t \).*

We now turn to the characterization of the wage Phillips curve in the short and long runs.

### 3.1 The Short-Run Wage Phillips Curve

The short-run wage Phillips curve is the locus of points \((u_t, \pi_t^W)\) satisfying equations (22) and (23) for a given value of the natural rate of unemployment \( u^n_t \).

To illustrate the properties of the short-run wage Phillips curve implied by the model, we consider a linear functional form for \( \gamma(j) \) and calibrate its parameters. Specifically, assume that

\[
\gamma(j) = (1 + \pi^*)^\delta (\Gamma_0 + \Gamma_1 j).
\]  

(24)

Here, the parameter \( \delta \in [0, 1] \) captures the degree of wage indexation to long-run inflation, and the parameters \( \Gamma_0, \Gamma_1 > 0 \) govern the degree of downward nominal wage rigidity. The time unit is a quarter. We set \( \Gamma_0 = 0.978 \) and \( \Gamma_1 = 0.031 \) to match the slope of the wage Phillips curve at a particular wage-inflation unemployment pair. Specifically, we target a slope of -0.74/4, which is consistent with the estimate presented in Galí and Gambetti (2019) for the United States over the period 1986 to 2007. Also, we target a steady-state rate of unemployment of 6 percent and a steady-state rate of inflation of 3 percent per year to match the average values observed in the United States over the period 1986 to 2007 (the sample period in Galí and Gambetti, 2019). That is, we assume that when \( \pi_t^W \) is equal to 3 percent per year, then \( u_t \) is equal to 6 percent and the slope of the wage Phillips curve is -0.74. We set the steady-state natural rate of unemployment at 4 percent \( (u^n = 0.04) \) and fix \( u^n_t \) at \( u^n \). We assume full indexation of wages \( (\delta = 1) \), as in much of the related literature. For example, Christiano, Eichenbaum, and Evans (2005) and Smets and Wouters (2007) assume that the weights on steady-state inflation and lagged inflation in the indexation scheme add up to one. Section 3.2 shows that when \( \delta = 1 \), the steady-state real allocation \((y_t, h_t, \text{and } u_t)\) is independent of the inflation rate. Finally, we set the elasticity of substitution across labor varieties to 11 \( (\eta = 11) \). This number is an average of the values used in Erceg, Henderson, and Levin (2000), Christiano, Eichenbaum, and Evans (2005), and Galí (2015). The top

The bottom panel of this table is discussed in section 4.

Figure 1 shows with a solid line the short-run wage Phillips curve implied by the calibrated heterogeneous downward nominal wage rigidity model in the space $(u_t, \pi_t^W)$. By construction, when the unemployment rate is 6 percent, the annual wage inflation rate is 3 percent. Also by construction, at that point, the slope of the Phillips curve is equal to -0.74. The predicted wage Phillips curve is convex, relatively steep at low levels of unemployment and relatively flat at high levels of unemployment. Thus the heterogeneous downward nominal wage rigidity model captures the empirical regularity first documented by Phillips, namely, that the relationship between unemployment and wage inflation is non-linear and, in particular, convex. Furthermore, Phillips hypothesized that the reason for the observed non-linearity was downward nominal wage rigidity, but he did not present a theoretical model with that feature. A contribution of the present paper is therefore to show that downward nominal wage rigidity can indeed give rise to a non-linear short-run wage Phillips curve.

Figure 1 also shows annual U.S. unemployment and wage inflation data for the period 1984 to 2023. The non-linearity of the Phillips curve, which was not targeted in

---

3 Annual wage inflation is computed as the average of year-over-year monthly wage inflation. The measure of monthly nominal wages is Average Hourly Earnings of Production and Nonsupervisory Employees, FRED series AHETPI. The annualized unemployment rate is the arithmetic mean of monthly unemployment rates, FRED series UNRATE. The observation labeled 2023 in the figure refers to unemployment and wage inflation in the first six months of 2023.
Figure 1: The Short-Run Wage Phillips Curve

Notes. The figure shows with a solid line the short-run wage Phillips curve implied by the calibrated heterogeneous downward nominal wage rigidity model. The figure also shows the \((u_t, \pi_t^W)\) pairs observed in annual U.S. data over the period 1984 to 2023.

The calibration—recall that the calibration targets only one point along the Phillips curve and the slope at that point—, captures relatively well the shape of the observed cloud of unemployment and wage inflation pairs. In particular, the post Covid-19 observations (2022 and 2023) characterized by high inflation and low unemployment fall reasonably close to the steep portion of the Phillips curve implied by the calibrated model.

Figure 2 displays how changes in key structural parameters of the model shift the short-run wage Phillips curve. A given level of unemployment requires a higher wage inflation rate the more downwardly rigid nominal wages are (the higher \(\Gamma_0\) and \(\Gamma_1\) are) and the higher the degree of wage indexation is (the higher \(\delta\) is). That is, an increase in any of these three parameters shifts the short-run Phillips curve up and to the right. The intuition behind these effects is as follows. Wage inflation acts as a lubricant of the labor market because the higher wage inflation is, the larger the number of activities that are not constrained by the wage lower bound will be. An increase in \(\Gamma_0\), \(\Gamma_1\), or \(\delta\) raises the wage lower bound. Thus, the economy needs more lubricant to maintain the same level of unemployment. (For the same reason, an increase in the inflation target \(\pi^*\) (not shown in Figure 2) moves the Phillips curve up and to the right.) Finally, an increase in the natural rate of unemployment shifts the short-run Phillips curve to the right, so that at every level of wage inflation the economy
Figure 2: Shifters of the Short-Run Wage Phillips Curve

Notes. Solid lines correspond to the baseline calibration. The parameters $\Gamma_0$, $\Gamma_1$, and $\delta$ pertain to the wage lower bound function $\gamma(j) = (1 + \pi^*)^\delta(\Gamma_0 + \Gamma_1 j)$ (equation 24). The parameter $u^n$ represents the natural rate of unemployment. The figure shows that the short-run wage Phillips curve shifts up and to the right when the degree of downward nominal wage stickiness increases ($\Gamma_0$ or $\Gamma_1$ increase), when the natural rate of unemployment rises ($u^n$ increases), or when the degree of wage indexation increases ($\delta$ increases).
3.2 The Long-Run Wage Phillips Curve

The long-run wage Phillips curve is the locus of points \((u_t, \pi^W_t) = (u, \pi^W)\) satisfying equations (22) and (23) for \(u^n_t = u^n\), where variables without a time subscript denote steady-state values. The difference between the short- and long-run Phillips curves is that in the long run wage inflation and price inflation are both equal to the inflation target. Specifically, because output is constant in the steady state, the Euler equation (17) implies the long-run Fisher relationship

\[ i = \frac{1 + \pi}{\beta} - 1. \]

This expression and the Taylor rule (19) imply that in the steady state inflation must be at its target level,

\[ \pi = \pi^*. \]

Since in the steady state the real wage is constant, equilibrium condition (20) implies that wage inflation equals product-price inflation,

\[ \pi^W = \pi^*. \]

Equilibrium conditions (22) and (23) evaluated at \(u_t = u\), \(\pi^W_t = \pi^*\), and \(u^n_t = u^n\) constitute a relationship between inflation and unemployment in the steady state, which we call the long-run wage Phillips curve. It follows immediately that in the absence of wage indexation, that is, when the function \(\gamma(\cdot)\) is independent of \(\pi^*\), the short- and long-run Phillips curves coincide. But this ceases to be the case when wages are indexed to steady-state inflation. To see this, consider again the linear functional form for \(\gamma(\cdot)\) given in equation (24). In this case, equilibrium conditions (22) and (23) evaluated at \(u_t = u\), \(\pi^W_t = \pi^*\), and \(u^n_t = u^n\), become

\[
(1 + \pi^W)^{(1-\eta)(1-\delta)} = j^* \gamma(j^*)^{1-\eta} + \int_{j^*}^{1} \tilde{\gamma}(j)_{1-\eta} dj,
\]

\[
u = u^n + (1 - u^n) \left[ (1 - j^*) - \int_{j^*}^{1} \left( \frac{\tilde{\gamma}(j)}{\gamma(j^*)} \right)^{-\eta} dj \right],
\]

where \(\tilde{\gamma}(j) \equiv \Gamma_0 + \Gamma_1 j\).

It is clear from (25) and (26) that under full wage indexation \((\delta = 1)\) the long-run wage Phillips curve is perfectly vertical in the space \((u, \pi^W)\). This is intuitive. Under full indexation, an increase in inflation fails to inject grease in the labor market in the long run,
Figure 3: The Long-Run Wage Phillips Curve

Notes. The parameter $\delta$ pertains to the wage lower bound function $\gamma(j) = (1 + \pi^*)^\delta(\Gamma_0 + \Gamma_1 j)$ (equation 24). The figure shows that the long-run wage Phillips curve is in general downward sloping and steeper than its short-run counterpart. The long-run wage Phillips curve is vertical when $\delta = 1$ and identical to the short-run wage Phillips curve when $\delta = 0$. 
as indexation soaks it up one for one. By contrast, under imperfect indexation ($\delta < 1$), only a fraction $\delta$ of an increase in inflation is absorbed by indexation and the rest is grease to the labor market.

To see more precisely what happens for intermediate degrees of wage indexation ($\delta \in (0, 1)$), Figure 3 displays the long-run wage Phillips curve for four different degrees of wage indexation and compares it to its short-run counterpart. The figure illustrates that absent full indexation the long-run wage Phillips curve is downward sloping and that as the degree of wage indexation goes down the slope of the long-run wage Phillips curve falls. In fact, the long-run wage Phillips curve rotates around the point $(u, \pi^W) = (0.06, 0)$ counterclockwise as $\delta$ declines. To see why this is so, recall that the calibration targets an unemployment rate of 6 percent and assumes full indexation. Therefore, the left-hand side of (25) is equal to 1, regardless of the value of $\pi^W$. This uniquely pins down the steady value of $j^*$ and by equation (26) also the steady state value of $u$. When $\delta < 1$ and inflation is zero ($\pi^W = 0$), then the left-hand side of equation (25) is also equal to 1, regardless of the value of $\delta$. Thus, the long-run wage Phillips curve must contain the point $(u, \pi^W) = (0.06, 0)$ for any value of $\delta$.

Comparing the long-run and the short-run Phillips curves, the figure shows that for positive degrees of wage indexation $\delta \in (0, 1]$, the long-run Phillips curve is steeper than its short-run counterpart. The intuition why the wage Phillips curve is steeper in the long run is as follows. In the short run, movements in the inflation rate are not accompanied by movements in the long-run rate of inflation, so they grease the labor market one for one. By contrast, to the extent that $\delta$ is greater than zero, only a fraction $(1 - \delta)$ of an increase in inflation greases the labor market in the long run.

4 How Important Is the Forward-Looking Component of the Wage Phillips Curve?

This section characterizes the equilibrium dynamics of the heterogeneous downward nominal wage rigidity (HDNWR) model and compares them to those implied by the new-Keynesian (NK) model of wage stickiness. Because an endogenous labor supply is a necessary feature of the latter model, to facilitate comparison, the section begins by endogenizing the labor choice in the former model.
4.1 The HDNWR Model with Endogenous Labor Supply

Suppose now that the representative household derives disutility from supplying labor. Specifically, replace the lifetime utility function considered thus far with the function

\[ E_0 \sum_{t=0}^{\infty} \beta^t \left[ U(c_t) - \int_0^1 V(h^{st}_t) dj \right], \quad (27) \]

where \( h^{st}_t \) denotes the amount of labor of type \( j \) supplied in period \( t \), and \( V(\cdot) \) is a convex labor disutility function. To facilitate aggregation, we use the functional form

\[ V(h) = \frac{h^{1+\theta}}{1 + \theta}, \quad (28) \]

which is often used in business-cycle analysis (e.g., Galí, 2015). As before, there is rationing in the labor market: for each labor type \( j \), at the going wage \( W_{jt} \) households may not be able to sell all the units of labor they offer. The household sets its desired supply of labor of variety \( j \) to equate the marginal rate of substitution between labor and consumption to the variety-specific real wage. Formally, the supply of labor of type \( j \) is given by

\[ \frac{V'(h^{st}_t)}{U'(c_t)} = w_{jt}, \quad (29) \]

where \( w_{jt} \equiv W_{jt}/P_t \). We continue to assume that there is an exogenous amount of involuntary unemployment unrelated to wage stickiness, embodied in the variable \( u^n_t \) denoting the natural rate of unemployment. The restriction that employment is voluntary now takes the form

\[ h_{jt} \leq h^{st}_t (1 - u^n_t). \quad (30) \]

This expression says that the household is not willing to have more members employed than the ones it voluntarily supplies to the market net of the ones that are naturally unemployed.

The household’s budget constraint and the optimality conditions associated with consumption and bond holdings are unchanged. The firm’s demand for labor of variety \( j \in [0, 1] \), given by equation (3) is also unchanged.

As before, we consider an equilibrium in which each period \( t \geq 0 \) there is a cut-off labor variety, \( j^*_t \), that operates at full employment,

\[ h_{j^*_t t} = h^{st}_{j^*_t t} (1 - u^n_t), \quad (31) \]
and for which the wage constraint holds with equality,

$$W_{j^*t} = \gamma(j^*t)W_{t-1}. \quad (32)$$

Combining these two conditions with the labor demand (3) and the labor supply (29) yields

$$V'(h_t - u_t) \left( \frac{\gamma(j^*t)}{\gamma(j^*t)^{1+\eta}} \right)^{-\eta} \left( \frac{\gamma(j^*t)}{\gamma(j^*t)^{1+\eta}} \right)^{-\eta} \left( \frac{\gamma(j^*t)}{\gamma(j^*t)^{1+\eta}} \right)^{-\eta} \left( \frac{\gamma(j^*t)}{\gamma(j^*t)^{1+\eta}} \right)^{-\eta} = \frac{\gamma(j^*t)w_{t-1}}{1 + \pi_t}. \quad (33)$$

It can be shown that, as in the case of an inelastic labor supply, all labor varieties $j < j^*_t$ operate at full employment and are paid the same wage as variety $j^*_t$. Also, all varieties $j > j^*_t$ are constrained by the wage lower bound and suffer unemployment above the natural rate.

The definition of a competitive equilibrium with an endogenous labor supply is then identical to that given in Definition 2, except that equation (21) is replaced by equation (33).

With an endogenous labor supply, the unemployment rate is the ratio of unemployed labor to the total labor supply. Formally,

$$u_t = \frac{\int_0^{j^*_t} (h^*_t - h_{jt}) dj}{\int_0^{j^*_t} h^*_t dj}.$$  

Using the functional form (28) for the disutility of labor and equations (3), (29), (31), and (32), we can rewrite the unemployment rate as

$$u_t = u^n_t + (1 - u^n_t) \left[ \frac{\int_{j^*_t}^{J_t} \left( \frac{\gamma(j)}{\gamma(j_t)} \right)^{\frac{1}{\eta}} - \left( \frac{\gamma(j)}{\gamma(j_t)} \right)^{-\eta}}{J_t^* + \int_{j^*_t}^{J_t} \left( \frac{\gamma(j)}{\gamma(j_t)} \right)^{\frac{1}{\eta}} dj} \right]. \quad (34)$$

Note that as the elasticity of labor supply approaches zero ($\theta \to \infty$), equations (33) and (34) converge to equations (21) and (23), and the model becomes the one with inelastic labor supply studied in sections 2 and 3.

The following definition summarizes the equilibrium with endogenous labor supply.

**Definition 3 (Competitive Equilibrium with Endogenous Labor Supply)** A competitive equilibrium in the economy with endogenous labor supply is a set of processes $j^*_t$, $y_t$, $h_t$, $u_t$, $w_t$, $i_t$, $\pi_t$, and $\pi^{W}_t$, satisfying (16)-(20), (22), (33), and (34), given the initial condition $w_{-1}$ and the stochastic processes $z_t$, $\mu_t$, and $w^n_t$.

As in the case of an inelastic labor supply, the model features a static wage Phillips curve
implicitly given by equations (22) and (34).

In spite of the fact that the model features occasionally binding constraints at the level of individual varieties of labor, the complete set of equilibrium conditions given in Definition 3 does not. This means that the model is amenable to a characterization of the equilibrium dynamics using perturbation methods. We summarize this result in the following proposition:

**Proposition 2 (HDNWR and Perturbation)** The equilibrium dynamics of the HDNWR model with inelastic or elastic labor supply described in Definitions 2 and 3, respectively, can be approximated using perturbation techniques.

Thus, to obtain the implied impulse responses of the model to exogenous shocks we can follow the customary approach of linearizing the equilibrium conditions around the nonstochastic steady state.

The quantitative analysis that follows adopts this approach. The calibration of the model is summarized in Table 1. The parameters appearing in the top panel of the table were already discussed in section 3. Because the model now features an endogenous labor supply, the parameters $\Gamma_0$ and $\Gamma_1$ were recalibrated using the same targets for the slope of the Phillips curve and steady-state unemployment. The implied values are $\Gamma_0 = 0.9781$ and $\Gamma_1 = 0.0310$, which are the same as those associated with the HDNWR model with inelastic labor supply up to the third significant digit.

We assume a period consumption subutility function of the form $U(c) = (c^{1-\sigma} - 1)/(1 - \sigma)$ and a production function of the form $F(h) = h^\alpha$. Following Galí (2015), we set $\sigma = 1$, $\alpha = 0.75$, $\beta = 0.99$, $\theta = 5$, $\alpha_\pi = 1.5$, and $\alpha_y = 0.5/4$.

### 4.2 Response to a Monetary Shock

We assume that the monetary shock follows an autoregressive process of order one

$$\ln \mu_t = \rho_\mu \ln \mu_{t-1} + \epsilon_\mu^t,$$

where $\epsilon_\mu^t$ is a mean zero i.i.d. innovation, and $\rho_\mu \in [0, 1)$ is a parameter. Following Galí (2015), we set $\rho_\mu = 0.5$.

Figure 4 displays with solid lines the impulse response to a one percent annualized increase in $\mu_t$. In equilibrium this monetary contraction results in a 0.11 percentage point increase in the policy interest rate. The increase in the interest rate is smaller than the increase in $\mu_t$ because of the contemporaneous adjustment of the endogenous variables that enter the Taylor rule, $\pi_t$ and $y_t$. The model predicts that the tightening in monetary conditions is deflationary. An efficient adjustment of the labor market would require a fall in nominal
wages large enough to perfectly offset the fall in prices. However, due to the presence of downward nominal wage rigidity, the decline in nominal wages is insufficient. That is, a larger number of job varieties become constrained by the lower bound on nominal wages. This frictional adjustment is reflected in a decline in the labor variety cutoff $j^*$. In turn, the fact that the real wage is inefficiently high for more labor varieties causes an increase in involuntary unemployment and hence a decline in output and consumption.

A key difference between the present model and the NK sticky wage model is that the Phillips curve implied by the former is static whereas the one implied by the latter is forward-looking. Here, we wish to ascertain whether this difference is relevant for the predicted equilibrium dynamics. To this end, we consider a canonical NK sticky-wage model that departs from the current model only in its wage setting module. Specifically, we assume that wages are set in a Calvo-Yun fashion as in Erceg, Henderson, and Levin (2000) and define the unemployment rate as in Gali (2011) and Casares (2010). A detailed derivation of the NK model we use here can be found in a technical appendix (Schmitt-Grohé and Uribe, 2022). All parameters of the NK model that are common to the present model are assigned the same values, namely, those given in Table 1. The common parameters are $\pi^*$, $\eta$, $\beta$, $\sigma$, $\theta$, $\alpha$, $\alpha_\pi$, $\alpha_y$, and $\rho_\mu$. As in the HDNWR model, we assume full indexation of wages to steady-state inflation.

It remains to explain how we calibrate the degree of nominal wage rigidity in the NK model. We cannot directly adopt the strategy used to calibrate the HDNWR model, namely, to match the slope of the implied wage Phillips curve to the one estimated by Gali and Gambetti (2019). The reason is that the empirical Phillips curve estimated by Gali and Gambetti is not forward looking and therefore does not have a natural theoretical counterpart in the NK model. Instead, we assume that the fraction of types of labor that cannot reoptimize wages in any given period in the NK model is equal to the steady-state fraction of types of labor that are stuck at the wage lower bound in the HDNWR model. Formally, letting $\theta_w$ denote the fraction of wages that are not set optimally in any given period in the NK model, we impose $\theta_w = 1 - j^*$, where $j^*$ is the deterministic steady-state value of $j^*_t$. The resulting value of $\theta_w$ is 0.35. This value is low relative to those typically used in the NK literature, which come to a large extent from full information DSGE estimation of NK models with forward-looking wage Phillips curves. For example, Gali (2015) sets $\theta_w$ to 0.75. To address this issue, we also consider a calibration in which $\theta_w = 1 - j^* = 0.75$.

Figure 4 displays with dashed lines the response of the NK model to a 1 percent per annum increase in the monetary shock $\mu_t$. The figure shows that for most variables the response of the NK and HDNWR models are quite close. This result is robust to using the more conventional higher degree of wage rigidity. Following Gali (2015), we increase $\theta_w$ from
Figure 4: Impulse Responses to a Monetary Tightening

Notes. Solid lines correspond to the HDNWR model and dashed lines to the NK model with Calvo wage stickiness. The size of the monetary shock is 1 percent per annum and its serial correlation is 0.5. The horizontal axes measure quarters after the shock.
0.35 to 0.75. To preserve comparability, we recalibrate the HDNWR model. Specially, we drop the requirement that it matches the slope of the Galí-Gambetti wage Phillips curve and instead target a value of 0.75 for $1 - j^*$. The resulting values of $\Gamma_0$ and $\Gamma_1$ are 0.9908 and 0.0175. Figure 5 displays the predicted impulse responses. Understandably, both models predict a more subdued response of wage inflation and a larger response of unemployment. The important point for the purpose of the present discussion, however, is that both models deliver quite similar dynamics.

The implication of this result is that the forward-looking nature of the wage Phillips curve in the NK framework does not appear to play a crucial role for equilibrium dynamics, at least for the calibrations considered here.

4.3 Response to a Technology Shock

Figure 6 displays the response of the HDNWR model to a 1-percent positive productivity shock (a 1 percent innovation in $z_t$). The shock is assumed to follow a first-order autoregressive process of the form

$$\ln z_t = \rho_z \ln z_{t-1} + \epsilon^z_t,$$

where $\epsilon^z_t$ is a mean-zero i.i.d. disturbance and $\rho_z$ is a parameter. Following Galí (2015), we set $\rho_z$ equal to 0.9.

The increase in output following the positive technology shock puts downward pressure on product-price inflation. The increase in labor productivity following the technological improvement pushes nominal wages up. This relaxes the wage constraint for some wage varieties ($j^*_t$ goes up on impact), inducing a fall in unemployment in the initial period. As the technology shock begins to return to its stationary position, real wages fall. However, due to the presence of wage rigidity, they fall at a slower pace than the one consistent with full employment. As a result, unemployment rises and remains above steady state throughout the transition.

The response of the NK model to the positive productivity shock, shown with dashed lines in Figure 6, is similar. The main difference is that under the present calibration in the NK model unemployment experiences a larger decline on impact and a smaller subsequent increase. This difference in the response of unemployment is due to the relatively low value picked for the degree of wage rigidity ($\theta_w = 0.35$). When we set $\theta_w$ to the more conventional value of 0.75 and recalibrate the HDNWR model accordingly, then the response of unemployment to the technological improvement is almost the same in both models. This result is shown in Figure 7. The two models produce virtually the same responses to the positive productivity shock not only for unemployment but also for most of the other endogenous
Figure 5: Impulse Responses to a Monetary Tightening with a Higher Degree of Wage Rigidity ($\theta_w = 1 - j^* = 0.75$)

Notes. Solid lines correspond to the HDNWR model and dashed lines to the NK model with Calvo wage stickiness. The size of the monetary shock is 1 percent per annum and its serial correlation is 0.5. The horizontal axes measure quarters after the shock.
Figure 6: Impulse Responses to a Productivity Shock

Notes. Solid lines correspond to the HDNWR model and dashed lines to the NK model with Calvo wage stickiness. The size of the shock is 1 percent and its serial correlation is 0.9.
Figure 7: Impulse Responses to a Productivity Shock with a Higher Degree of Wage Rigidity ($\theta_w = 1 - j^* = 0.75$)

Notes. Solid lines correspond to the HDNWR model and dashed lines to the NK model with Calvo wage stickiness. The size of the shock is 1 percent and its serial correlation is 0.9.
variables displayed in the figure. Overall, the results of the present section indicate that the forward looking component in the NK wage Phillips curve does not play a central role in shaping the impulse responses to monetary and productivity shocks.

5 Conclusion

A distinctive feature of the NK model is an expectations augmented wage Phillips curve. Yet, it is not clear what role this feature plays in shaping macroeconomic dynamics. This paper makes a step toward putting the forward-looking nature of the NK wage Phillips curve into perspective.

The forward-looking component of the new-Keynesian wage Phillips curve is due to the assumption that workers have market power. This assumption is not compelling in economies without a strong labor union presence like the United States. This paper establishes that the assumption that workers have market power is not a necessary ingredient to obtain a meaningful relationship between unemployment and wage inflation in optimizing models with nominal rigidity and forward-looking agents. It does so by building a model with heterogeneous downward nominal wage rigidity that nests as a special case the standard (homogeneous) downward nominal wage rigidity framework. The model with heterogeneous downward nominal wage rigidity delivers a non-forward-looking wage Phillips curve and is amenable to analysis using perturbation methods.

Under standard calibrations the proposed model delivers equilibrium dynamics in response to monetary and technology shocks that are qualitatively and quantitatively similar to those implied by the NK model of wage stickiness. This result suggests that a forward-looking component in the wage Phillips curve does not necessarily play a critical role for the predicted dynamic behavior of key macroeconomic indicators.
